Aims and objectives

Breast compression during mammography is necessary to produce an image of diagnostic quality [1,2]. Effective compression spreads out overlapping tissues to enable better visualisation of breast structures; compression also reduces breast thickness, which minimises radiation to the breast [3]. Good radiographic technique ensures that the maximum amount of breast tissue is imaged adequately so as to optimise lesion visualisation.

There is no consensus in the literature regarding the position for the image receptor (IR) during the exposure for the cranio caudal (CC) projection. Some authors suggest the IR be located at the infra mammary fold (IMF), whilst others indicate it can be elevated slightly from the IMF [4,5]. The intention of elevating the IR relative to the IMF is to increase the area of breast tissue (the 'breast footprint') on the IR. This action would bring the breast closer to the IR and potentially enhance image quality by reducing geometric unsharpness. Additionally, elevating IR relative to IMF might improve the balance of pressure on the breast from above and from below, which could result in the procedure being less uncomfortable, as noted by Hogg et al in 2013 [6]. Despite IMF elevation being proposed within the literature no human study has been performed to determine whether the breast footprint increases or pressure balance improves when the IR is elevated.

In 2013 Hogg et al [6] conducted a phantom study to validate a proposed method to determine the effect of changing the relative positions of the IMF and IR on the breast footprint and pressure balance. The study demonstrated that as IMF is elevated the footprint of the breast phantom increases and a better balance of pressure can be achieved. The paper concluded by suggesting that a human study should be conducted to establish whether the phantom findings hold true in human females. In this paper we used the method described by Hogg et al [6] on a cohort of 15 human females (30 breasts). Our aim was to evaluate breast footprint and pressure balance with IR at IMF and IR 2cm above the IMF.
Methods and materials

The study was approved as service evaluation by University Hospitals of Morecambe Bay NHS Foundation Trust UHMB; ethical approval was granted by the University of Salford. All women aged 47 to 66 employed by University Hospitals of Morecambe Bay NHS Foundation Trust UHMB were invited to take part in the study. After applying exclusion criteria, 16 participants were selected. Exclusion criteria were: previous breast surgery; pacemaker; current breast symptoms; local skin conditions; currently under investigation for possible breast cancer; breast bra cup size less than 5. A GE Senographe Essential full field digital mammography (FFDM) with a 24x30 cm fixed compression paddle was used. Mammograms were not required for this study.

Using an Xsensor pressure mapping device [7], which comprises of an array of pressure sensors with a resolution of 1.6129 cm (Figure 1), the breast phantom method described by Hogg et al was adopted to collect human data. The Xsensor is a pressure mapping tool in the form of a flexible mat which records, in real time, the pressure (in mmHg) between two contacting surfaces. In this case the interface pressure was recorded between the IR and under-surface of the breast and between the compression paddle and the upper surface of the breast. Pressure readings were taken with the Xsensor pressure mat wrapped around participant breasts (Figure 1).

For each participant, for left and right breasts, the pressure between the breast and compression paddle and between the breast and the image receptor, and breast footprint on IR with IR at IMF and IR at 2cm above IMF were recorded. For all participants a compression force of 80N was applied to the breasts. Two experienced female Health and Care Professions Council registered radiographers qualified in mammography carried out the breast compressions[ 8]. To simulate clinical conditions each radiographer was instructed to use their normal technique for 'IR at IMF'. IMR +2cm was achieved by elevating the IR by 2cm whilst repositioning the compression paddle. For consistency, one radiographer performed the left breast compressions; the other radiographer performed the right breast compressions. In order to minimise the potential for artefacts in the pressure map data one radiographer performed the participant positioning and compression, the other ensured that there were no creases in the pressure mat.

Each participant received four separate breast compressions, two for each breast. A drop in compression force values displayed on the mammography unit was observed for several seconds after the compression force was initially applied; this phenomenon has been noted previously by Hauge et al [9]. It was therefore necessary to adjust the compression force until a steady reading of 80N was maintained. Once the pressure was stable Xsensor pressure data was recorded for 5 seconds.

Data for the 15 participants was transferred from the Xsensor acquisition module to a password protected laptop computer. Pressure mat data was visually displayed as 2D images, where blue signifies low and red signifies high pressure readings (Figure 2).
Data was also recorded as matrices of pixel values in mmHg to allow analysis of the data, which was performed using Excel.

Data cleaning and analysis
Prior to analysis the numeric data within Excel was examined to remove any artefacts. This involved deleting data points not attributable to pressure on the breast. These data points sat outside the breast area and were created by creases in the Xsensor pressure mat.

For each position ('at IMF' and 'IMF + 2cm') the following measurements were made: paddle and detector footprints (cm²), percentage of area on IR and average pressure on the paddle and detector (mmHg).

Using these values the uniformity index [6] was calculated where:

\[
\text{Uniformity Index (UI)} = \frac{(A-B)}{(A+B)}
\]

Where:
A = average pressure per unit area applied by the paddle (mmHg/cm²)
B = average pressure per unit area applied by the detector (mmHg/cm²)

The UI value has the following implications. If UI = 0, there is equal pressure per unit area from the IR and the paddle (equal distribution); if 0<UI>1, there is greater pressure per unit area from the paddle on the top of the breast, with 1= all pressure per unit area is applied by the paddle; if -1<UI>0, there is greater pressure per unit area from the IR on the underside of the breast, with -1= all pressure per unit area is applied by the IR.

The difference between the area, percentage area, average pressure and UI were calculated between the two positions, and comparisons were made between the radiographers (right and left breast).

Results

Figure 2 illustrates an image of the pressure distribution at the 'breast/paddle' and 'breast/IR' interfaces, with IR at +2 cm; Figure 3 illustrates an image of the pressure distribution with the IR at IMF.

The difference in breast footprint ($\text{cm}^2$) between IR at IMF and IR +2 cm is demonstrated in Figure 4 and Table 1. It is clear that for both left and right breasts, there is a significant increase in IR breast footprint when IR is raised by 2 cm; on average this increase is 13.81 cm$^2$ ($p<0.02$). No significant difference was found for the paddle breast footprint when raising the IR by 2 cm, with an average decrease in area of 1.06 cm$^2$ ($p>0.26$). Figure 5 and Table 2 illustrate these differences in terms of percentage increase in area. For left and right breasts, IR breast footprint percentage area increases significantly by 13.81% ($p<0.02$) when IR is raised by 2 cm. By contrast there is no significant change in percentage area on the paddle when the IR is raised by 2 cm (-0.81% ($p=0.51$). Figure 6 and Table 3 illustrate the percentage difference in pressure between IR at IMF and IR +2 cm. As can be seen there are significant differences, however the changes are small in comparison to the increase in footprint. On average the pressure decreased by 0.04% ($p<0.05$) when IR was raised to +2.

Figure 7 and Table 4 show the uniformity index for IR at IMF and IR +2 cm. As shown, the UI was closer to zero when the IR was positioned at +2 cm. On average there was a significant difference between the UI, which was 0.04 for IR at IMF and 0.00 for IR +2 cm ($p = 0.04$).

All graphs have the following legend:
LCC D IR = left breast, Image receptor
RCC D IR = right breast, Image receptor
Ave D IR = average of left and right breast, Image receptor
LCC P = left breast, paddle
RCC P = right breast, paddle
Ave P = average of left and right breast, paddle
Total = average between left and right breast, paddle and image receptor
At IMF is the baseline

Breast footprint increases significantly when the IR is raised by 2 cm from the IMF. There are significant pressure differences between IR at IMF and IR at IMF +2 cm, however these changes are small in comparison to the increase in footprint. UI at IR +2 cm is close to zero, compared with IR at IMF, suggesting a better balance when the IR is raised by 2 cm. Overall, raising the IR by 2 cm appears to be justified.

Differences existed between left and right breasts. These differences could be due to asymmetry between the left and right breasts, or differences in radiographer technique.
Female breasts are rarely the same shape or volume and variation is common [10-12], which might help explain our findings. As part of our study we could not assess breast volume or shape because bra size is not a reliable indicator of breast size [13-16]. Further work should be considered to examine the potential effects that asymmetry (shape and volume) might have on pressure, UI and IR footprint.

Differences in compression forces used in mammography have been reported within and between practitioners [17-19]; these differences are likely to be explained by underlying differences in technique [20]. Although the same compression force was applied throughout this experiment, if other differences in technique did exist between the two radiographers in our study then this might explain why UI and pressure were different between left and right breast and this could represent a limitation to our work. Conversely, if practitioner differences are the explanation for UI and pressure differences, between left and right breasts, then this could add external validity to our work by reflecting clinical reality as for both left and right breasts and therefore for both practitioners, breast footprint on the IR increased when the IR was elevated by 2 cm from the IMF.

Conclusion

The data suggests that raising the IR by 2cm relative to IMF increases the breast footprint on the IR, gives a better pressure balance between breast/IR and breast/paddle and gives a uniformity index close to zero. On this basis practitioners should consider raising the IR by 2 cm relative to the IMF in the clinical practice. Further work is suggested to investigate the effects of practitioner variability and breast asymmetry for breast footprint on IR, pressure balance between IR/breast and paddle/breast and UI.
